

# **Functional Programming**

Week 4 - Polymorphism

René Thiemann Jonathan Bodemann James Fox Joshua Ocker Daniel Rainer Daniel Ranalter Christian Sternagel

Department of Computer Science

## **List Examples**

- task 1: append two lists, e.g., appending [1,5] and [3] yields [1,5,3]
- prerequisite: concrete representation of abstract lists in Haskell
   data List = Empty | Cons Integer List
   -- abstract list [1,5] is represented as Cons 1 (Cons 5 Empty)
- solution to task 1: pattern matching and recursion on first argument

```
append Empty ys = ys append (Cons x xs) ys = Cons x (append xs ys)
```

interpretation of the second equation

- first append the remaining list xs and ys (append xs ys),
   afterwards insert x in front of the result
- task 2: determine last element of list
- solution: consider three cases (list with at least two elements, singleton list, empty list)

#### Last Lecture

- function definitions by pattern matching
  - allow several equations for each function
  - equations are tried from top to bottom
- patterns
  - x, \_, CName pat1 ... patN, x@pat
  - variable names must be distinct
  - patterns describe shape of inputs
- recursion
  - in a defining equation of function f one can use f already in the rhs

```
f pat1 ... patN = ... (f expr1 ... exprN) ...
```

• the arguments in each recursive call should be smaller than in the lhs

RT et al. (DCS @ UIBK) Week 4 2/22

## Example - Datatypes Expr and List

consider datatype for expressions

```
data Expr = Number Integer | Plus Expr Expr | Negate Expr
```

- task: create list of all numbers that occur in expression
- solution

```
numbers :: Expr -> List
numbers (Number x) = Cons x Empty
numbers (Plus e1 e2) = append (numbers e1) (numbers e2)
numbers (Negate e) = numbers e
```

- remarks
  - the rhs of the first equation must be Cons x Empty and not just x: the result must be a list of numbers
  - numbers (and also append) is defined via structural recursion:
     invoke the function recursively for each recursive argument of a datatype
     (e1 and e2 for Plus e1 e2, and e for Negate e, but not x of Number x)

RT et al. (DCS @ UIBK) Week 4 4/22

### **Decomposition and Auxiliary Functions**

- during the definition of new functions, often some functionality is missing
- task: define a function to remove all duplicates from a list
- solution:

```
remdups Empty = Empty
 remdups (Cons x xs) = Cons x (remove x (remdups xs))
 -- subtask: define "remove x xs" to delete each x from list xs
 remove x Empty = Empty
 remove x (Cons y ys) = rHelper (x == y) y (remove x ys)
 rHelper True _ xs = xs
 rHelper False y xs = Cons y xs
remarks
```

solution above uses structural recursion: remdups (Cons x xs) invokes remdups xs

alternative solution with non-structural recursion: replace 2nd equation by

```
remdups (Cons x xs) = Cons x (remdups (remove x xs))
```

RT et al. (DCS @ UIBK) RT et al. (DCS @ UIBK) Week 4 5/22 Week 4 6/22

## **Limitations of Datatype Definitions**

• task: define a datatype for lists of numbers and a function to compute their length

```
data IntList = EmptyIL | ConsIL Integer IntList
lenIL EmptyIL
lenIL (ConsIL xs) = 1 + lenIL xs
```

• task: define a datatype for lists of strings and a function to compute their length

```
data StringList = EmptySL | ConsSL String StringList
lenSL EmptvSL
lenSL (ConsSL xs) = 1 + lenSL xs
```

- observations
  - the datatype and function definitions are nearly identical: only difference is type of elements (Integer/String) and type/function/constructor names
  - creating a copy for each new element type is not desirable for many reasons
    - writing the same functionality over and over again initially is tedious and error-prone
    - changing the implementation later on is even more tedious and error-prone integrate changes for every element type
  - aim: define one generic list datatype and functions on these generic lists polymorphism

## Two Kinds of Polymorphism

- parametric polymorphism
  - key idea: provide one definition that can be used in various ways
  - - a datatype definition for arbitrary lists (parametrized by type of elements)

Parametric Polymorphism

- a datatype definition for arbitrary pairs (parametrized by two types)
- a function definition that works on parametric lists, pairs, ...; examples: length, append two lists, first component of pair, ...
- ad-hoc polymorphism
  - key idea: provide similar functionality under same name for different types
  - examples
    - (==) is equality operator; different implementations for strings, integers, floats, ...
    - (+) is addition operator; different implementations for integers, floats, ...
    - minBound gives smallest value for bounded types; different implementations for Int, Char, ...
  - advantage: uniform access (instead of ==Int, ==String, ==Double)

RT et al. (DCS @ UIBK) RT et al. (DCS @ UIBK) Week 4 7/22 Week 4 8/22

#### Type Variables

- definition of polymorphic types and functions requires type variables
- type variables
  - start with a lowercase letter; usually a single letter is used, e.g., a, b, . . .
  - a type variable represents any type
  - type variables can be substituted by (more concrete) types
- type ty1 is more general than ty2 if ty2 can be obtained from ty1 by a type substitution
- important: it is allowed to replace generic types with more concrete ones; whenever expr :: ty1 and ty1 is more general than ty2 then expr :: ty2
- types ty1 and ty2 are equivalent if ty1 is more general than ty2 and vice versa
- examples

RT et al. (DCS @ UIBK)

• a is more general than any other type

```
a -> b -> a is more general than Int -> Char -> Int, a -> Bool -> a, c -> c -> a/Int, b/Char a/a, b/Bool a/c, b/c
a -> b -> a is equivalent to b -> a -> b
a -> b -> a is not more general than a -> b -> c
someFun True x y = x is a function with type Bool -> b -> c -> b
```

Week 4

Class Assertions and Predefined Type Classes

often a type variable a needs to be constrained to belong to a certain type class

```
a type a for which (+), (-), (*) is defined:
a type a for which (/) is defined:
a type a for which (==), (/=) is defined:
a type a for which (<), (<=), ... is defined:</li>
a type class Eq a
a type a for which (<), (<=), ... is defined:</li>
a type class Ord a
a type a for which show :: a -> String is defined:
type class Show a
```

- these constraints are called class assertions in Haskell, notation via =>
- examples

```
f x y = x
g x y = x + y - 3
h x y = "cmp is " ++ show (x < y) -- h :: Ord a => a -> a -> String
i x = "result: " ++ show (x + 3) -- i :: (Num a, Show a) => a -> String
```

- type substitutions need to respect class assertions
  - g False True is not allowed since Bool is not an instance of Num
  - i (5 :: Int) is allowed since Int is an instance of both Num and Show

## **Types Revisited**

- already known: definition of (basic) Haskell expressions and patterns
- now: definition of types
- prerequisite: type constructors (TConstr)
  - similarity to (value-)constructors (Cons. True, ...)
    - start with uppercase letter
    - have a fixed arity
  - difference to constructors: type constructors are used to construct types
- a Haskell type has one of the following three shapes

```
a a type variable
TConstr ty1 ... tyN a type constructor of arity N applied to N types
(ty) parentheses are allowed
examples (type constructors of arity 0: Char, Bool, Integer, ...; arity 2: ->)
-> without the two arguments is not a type
a -> Int - type of functions that take an arbitrary input and deliver an Int
Bool -> (a -> Int) - type of f. that take a Bool and deliver a f. of type a -> Int
Bool -> a -> Int - same as above (!), -> associates to the right
(Bool -> a) -> Int - take a function of type Bool -> a as input, deliver an Int
```

10/22

# Datatypes with Parametric Polymorphism

previous definition

RT et al. (DCS @ UIBK)

9/22

```
data TName =
        CName1 type1_1 ... type1_N1
        | ...
        | CNameM typeM_1 ... typeM_NM

• new definition

data TConstr a1 ... aK =
        CName1 type1_1 ... type1_N1
        | ...
        | CNameM typeM_1 ... type1_NM

• new definition is more general (K can be zero)
• a1 ... aK have to be distinct type variables
• TConstr is a new type constructor with arity K
• a1 ... aK can be used in any of the types typeI_J, but no other type variables
• CName1 :: type1_1 -> ... -> type1_N1 -> TConstr a1 ... aK, etc.
```

RT et al. (DCS @ UIBK) Week 4 11/22 RT et al. (DCS @ UIBK) Week 4 12/22

# Examples using Parametric Polymorphism

```
RT et al. (DCS @ UIBK) Week 4
```

#### **Functions on Parametric Lists**

#### Parametric Lists

RT et al. (DCS @ UIBK)

13/22

```
data List a = Empty | Cons a (List a)

    List is unary type constructor

    example types

      • List a - list of arbitrary elements
      • List Integer - list of integers
      • List Bool - list of Booleans
      • List (List Integer) - list whose elements are lists of integers

    type of constructors

      • Empty :: List a
      • Cons :: a -> List a -> List a

    example values

      • Empty :: List a, Empty :: List Integer, Empty :: List (List Bool), ...
      • Cons 7 (Cons 5 Empty) :: List Integer, Cons True Empty :: List Bool, ...
      • Cons (Cons 7 (Cons 5 Empty)) (Cons Empty
                                                           Empty ):: List (List Int)
                              Int List Int
                                                 List Int List (List Int)
                                                  List (List Int)
      • Cons True (Cons 7 Empty)
                                                         not allowed, cannot mix element types
```

#### Parametric Lists Continued

data List a = Empty | Cons a (List a)

```
    function definitions can enforce certain class assertions
    example: replace all occurrences of x by y in a list
    replace :: Eq a => a -> a -> List a -> List a
    replace _ _ Empty = Empty
    replace x y (Cons z zs) = rHelper (x == z) y z (replace x y zs)
    rHelper True y _ xs = Cons y xs
    rHelper False _ z xs = Cons z xs
    class assertion Eq a => is required since list elements are compared via ==
    function definitions can enforce a concrete element type
```

example: replace all occurrences of 'A' by 'B' in a list

replaceAB :: List Char -> List Char
replaceAB xs = replace 'A' 'B' xs

 important: since replace asserts class Eq a, and this a is instantiated by Char in replaceAB, it is checked that Char indeed is in type class Eq

RT et al. (DCS @ UIBK) Week 4 15/22 RT et al. (DCS @ UIBK) Week 4 16/22

```
Lists in Haskell
```

- the list type from previous three slides is actually predefined in Haskell
- only difference: names

```
• instead of List a one writes [a]
```

- instead of Empty one writes []
- instead of Cons x xs one writes x : xs

in total

```
data [a] = [] | a : [a]
```

• list constructor (:) associates to the right:

```
1:2:3:[] = 1:(2:(3:[]))
```

- special list syntax for finite lists: [1, 2, 3] = 1 : 2 : 3 : []
- example: append on Haskell lists

```
append :: [a] -> [a] -> [a]
append [] ys = ys
```

append (x : xs) ys = x : append xs ys

RT et al. (DCS @ UIBK) Week 4

## Tuples in Haskell

- tuples are predefined in Haskell (so there is no need to define Pair, Triple, ...)
- for every  $n \neq 1$  Haskell provides:

```
• a type constructor ( , ..., )
• a (value) constructor ( , ..., )
```

examples

- Pair a b and Triple a b c are equivalent to (a, b) and (a, b, c) • (5, True, "foo") :: (Int, Bool, String)
- () :: ()
- (5) is just the number 5, so no 1-tuple
- (1, 2, 3) is neither the same as ((1, 2), 3) nor as (1, (2, 3))
- example program from previous slide using predefined tuples

```
findY :: [(Char, a)] -> a
findY []
                   = error "cannot find y"
findY (('y', v) : _) = v
findY ( : xs)
               = findY xs
```

#### **Tuples**

RT et al. (DCS @ UIBK)

RT et al. (DCS @ UIBK)

17/22

(with n entries)

(with n entries)

(and: is called "Cons")

- tuples are a frequently used datatype to provide several outputs at once; example: a division-with-remainder function should return two numbers. the quotient and the remainder
- it is easy to define various tuples in Haskell

```
data Unit = Unit
                                  -- tuple with 0 entries
data Pair a b = Pair a b
                                  -- tuple with 2 entries
data Triple a b c = Triple a b c -- tuple with 3 entries
```

• example: find value of key 'y' in list of key/value-pairs

```
findY :: [Pair Char a] -> a
                       = error "cannot find v"
findY []
findY (Pair 'y' v : _) = v
findY (_ : xs)
                       = findY xs
```

remark: one would usually define a function to search for arbitrary keys

Week 4

```
data Maybe a = Nothing | Just a
```

- Maybe is predefined Haskell type to specify optional results
- example application: safe division without runtime errors

```
divSafe :: Double -> Double -> Maybe Double
divSafe \times 0 = Nothing
divSafe x y = Just (x / y)
data Expr = Plus Expr Expr | Div Expr Expr | Number Double
eval :: Expr -> Maybe Double
eval (Number x) = Just x
eval (Plus x y) = plusMaybe (eval x) (eval y)
eval (Div x y) = divMaybe (eval x) (eval y)
plusMaybe (Just x) (Just y) = Just (x + y)
plusMaybe _ _
                            = Nothing
divMaybe (Just x) (Just y) = divSafe x y
divMaybe _ _
                           = Nothing
```

Week 4

RT et al. (DCS @ UIBK) Week 4 19/22 20/22

18/22

```
data Either a b = Left a | Right b
   • Either is predefined Haskell type for specifying alternative results
   • example application: model optional values with error messages
     divSafe :: Double -> Double -> Either String Double
     divSafe \times 0 = Left ("don't divide" ++ show \times ++ " by 0")
     divSafe x y = Right (x / y)
     data Expr = Plus Expr Expr | Div Expr Expr | Number Double
     eval :: Expr -> Either String Double
     eval (Number x) = Right x
     eval (Plus x y) = plusEither (eval x) (eval y)
     eval (Div x y) = divEither (eval x) (eval y)
     divEither (Right x) (Right y) = divSafe x y
     divEither e@(Left _) _
                                     = e
                                              -- new case analysis required
     divEither _ e
                                     = e
     plusEither ... = ...
RT et al. (DCS @ UIBK)
                                       Week 4
```

## Summary

RT et al. (DCS @ UIBK)

21/22

- usage of type variables and parametric polymorphism
  - datatypes with type variables
  - polymorphic functions, potentially include class assertions
     (example: f :: (Eq a, Show b) => a -> Bool -> a -> b -> String, ...)
- predefined datatypes
  - lists [a]
  - tuples (..,..,..)
  - option type Maybe a
  - sum type Either a b
- predefined type classes
  - arithmetic except division: Num a
  - arithmetic including division: Fractional a
  - equality between elements: Eq a
  - smaller than and greater than: Ord a
  - conversion to Strings: Show a

Week 4 22/22
